03.10-Working-With-Strings

November 10, 2024

1 Vectorized String Operations

One strength of Python is its relative ease in handling and manipulating string data. Pandas builds on this and provides a comprehensive set of *vectorized string operations* that are an important part of the type of munging required when working with (read: cleaning up) real-world data. In this chapter, we'll walk through some of the Pandas string operations, and then take a look at using them to partially clean up a very messy dataset of recipes collected from the internet.

1.1 Introducing Pandas String Operations

We saw in previous chapters how tools like NumPy and Pandas generalize arithmetic operations so that we can easily and quickly perform the same operation on many array elements. For example:

```
[1]: import numpy as np
x = np.array([2, 3, 5, 7, 11, 13])
x * 2
```

[1]: array([4, 6, 10, 14, 22, 26])

This *vectorization* of operations simplifies the syntax of operating on arrays of data: we no longer have to worry about the size or shape of the array, but just about what operation we want done. For arrays of strings, NumPy does not provide such simple access, and thus you're stuck using a more verbose loop syntax:

```
[2]: data = ['peter', 'Paul', 'MARY', 'gUIDO']
[s.capitalize() for s in data]
```

[2]: ['Peter', 'Paul', 'Mary', 'Guido']

This is perhaps sufficient to work with some data, but it will break if there are any missing values, so this approach requires putting in extra checks:

```
[3]: data = ['peter', 'Paul', None, 'MARY', 'gUIDO']
[s if s is None else s.capitalize() for s in data]
```

[3]: ['Peter', 'Paul', None, 'Mary', 'Guido']

This kind of manual approach is not only verbose and inconvenient, it can be error-prone.

Pandas includes features to address both this need for vectorized string operations and the need for correctly handling missing data via the str attribute of Pandas Series and Index objects

containing strings. So, for example, if we create a Pandas Series with this data we can directly call the str.capitalize method, which has missing value handling built in:

```
[4]: import pandas as pd
names = pd.Series(data)
names.str.capitalize()
```

```
[4]: 0 Peter
1 Paul
2 None
3 Mary
4 Guido
dtype: object
```

1.2 Tables of Pandas String Methods

If you have a good understanding of string manipulation in Python, most of the Pandas string syntax is intuitive enough that it's probably sufficient to just list the available methods. We'll start with that here, before diving deeper into a few of the subtleties. The examples in this section use the following Series object:

1.2.1 Methods Similar to Python String Methods

Nearly all of Python's built-in string methods are mirrored by a Pandas vectorized string method. Here is a list of Pandas str methods that mirror Python string methods:

len()	lower()	translate()	islower()
ljust()	upper()	startswith()	<pre>isupper()</pre>
rjust()	find()	<pre>endswith()</pre>	<pre>isnumeric()</pre>
center()	rfind()	<pre>isalnum()</pre>	<pre>isdecimal()</pre>
zfill()	<pre>index()</pre>	isalpha()	split()
strip()	rindex()	<pre>isdigit()</pre>	rsplit()
rstrip()	<pre>capitalize()</pre>	isspace()	<pre>partition()</pre>
<pre>lstrip()</pre>	<pre>swapcase()</pre>	<pre>istitle()</pre>	<pre>rpartition()</pre>

Notice that these have various return values. Some, like lower, return a series of strings:

But some others return numbers:

dtype: object

```
[7]: monte.str.len()
[7]: 0
           14
     1
           11
     2
           13
     3
            9
     4
           11
     5
           13
     dtype: int64
    Or Boolean values:
[8]: monte.str.startswith('T')
[8]: 0
           False
     1
          False
     2
            True
     3
           False
     4
            True
           False
     dtype: bool
    Still others return lists or other compound values for each element:
[9]: monte.str.split()
[9]: 0
           [Graham, Chapman]
              [John, Cleese]
     1
     2
            [Terry, Gilliam]
     3
                 [Eric, Idle]
     4
              [Terry, Jones]
            [Michael, Palin]
     dtype: object
```

We'll see further manipulations of this kind of series-of-lists object as we continue our discussion.

1.2.2 Methods Using Regular Expressions

In addition, there are several methods that accept regular expressions (regexps) to examine the content of each string element, and follow some of the API conventions of Python's built-in re module:

Method	Description
match	Calls re.match on each element, returning a
	Boolean.

Method	Description
extract	Calls re.match on each element, returning matched groups as strings.
findall	Calls re.findall on each element
replace	Replaces occurrences of pattern with some other
_	string
contains	Calls re.search on each element, returning a
	boolean
count	Counts occurrences of pattern
split	Equivalent to str.split, but accepts regexps
rsplit	Equivalent to str.rsplit, but accepts regexps

With these, we can do a wide range of operations. For example, we can extract the first name from each element by asking for a contiguous group of characters at the beginning of each element:

```
[10]: monte.str.extract('([A-Za-z]+)', expand=False)
```

```
[10]: 0 Graham
1 John
2 Terry
3 Eric
4 Terry
5 Michael
dtype: object
```

Or we can do something more complicated, like finding all names that start and end with a consonant, making use of the start-of-string (^) and end-of-string (\$) regular expression characters:

```
[11]: monte.str.findall(r'^[^AEIOU].*[^aeiou]$')
```

```
[11]: 0 [Graham Chapman]
1 []
2 [Terry Gilliam]
3 []
4 [Terry Jones]
5 [Michael Palin]
dtype: object
```

The ability to concisely apply regular expressions across Series or DataFrame entries opens up many possibilities for analysis and cleaning of data.

1.2.3 Miscellaneous Methods

Finally, there are some miscellaneous methods that enable other convenient operations:

Method	Description
get	Indexes each element

Method Description		
slice	Slices each element	
slice_replace	Replaces slice in each element with the passed value	
cat	Concatenates strings	
repeat	Repeats values	
normalize	Returns Unicode form of strings	
pad	Adds whitespace to left, right, or both sides of strings	
wrap	Splits long strings into lines with length less than a given width	
join	Joins strings in each element of the Series with the passed separator	
get_dummies	Extracts dummy variables as a DataFrame	

Vectorized item access and slicing The get and slice operations, in particular, enable vectorized element access from each array. For example, we can get a slice of the first three characters of each array using str.slice(0, 3). Note that this behavior is also available through Python's normal indexing syntax; for example, df.str.slice(0, 3) is equivalent to df.str[0:3]:

```
[12]: monte.str[0:3]
```

[12]: 0 Gra

1 Joh

2 Ter

3 Eri

4 Ter

5 Mic

dtype: object

Indexing via df.str.get(i) and df.str[i] are likewise similar.

These indexing methods also let you access elements of arrays returned by split. For example, to extract the last name of each entry, we can combine split with str indexing:

```
[13]: monte.str.split().str[-1]
```

[13]: 0 Chapman
1 Cleese
2 Gilliam
3 Idle
4 Jones
5 Palin
dtype: object

Indicator variables Another method that requires a bit of extra explanation is the get_dummies method. This is useful when your data has a column containing some sort of coded indicator. For example, we might have a dataset that contains information in the form of codes, such as A = "born in America," B = "born in the United Kingdom," C = "likes cheese," D = "likes spam":

```
[14]:
                            info
                    name
         Graham Chapman
                          B|C|D
      0
             John Cleese
      1
                             BID
      2
          Terry Gilliam
                             AIC
      3
               Eric Idle
                             BID
             Terry Jones
      4
                             BIC
      5
          Michael Palin B|C|D
```

The get_dummies routine lets us split out these indicator variables into a DataFrame:

```
[15]: full_monte['info'].str.get_dummies('|')
```

```
[15]:
           Α
               1
           0
                   1
       1
           0
       2
           1
               0
       3
           0
               1
                   0
       4
           0
               1
                   1
                      0
       5
           0
               1
                   1
```

With these operations as building blocks, you can construct an endless range of string processing procedures when cleaning your data.

We won't dive further into these methods here, but I encourage you to read through "Working with Text Data" in the Pandas online documentation, or to refer to the resources listed in Further Resources.

1.3 Example: Recipe Database

These vectorized string operations become most useful in the process of cleaning up messy, real-world data. Here I'll walk through an example of that, using an open recipe database compiled from various sources on the web. Our goal will be to parse the recipe data into ingredient lists, so we can quickly find a recipe based on some ingredients we have on hand. The scripts used to compile this can be found at https://github.com/fictivekin/openrecipes, and the link to the most recent version of the database is found there as well.

This database is about 30 MB, and can be downloaded and unzipped with these commands:

```
[16]: # repo = "https://raw.githubusercontent.com/jakevdp/open-recipe-data/master" # !cd data && curl -O {repo}/recipeitems.json.gz # !gunzip data/recipeitems.json.gz
```

The database is in JSON format, so we will use pd.read_json to read it (lines=True is required for this dataset because each line of the file is a JSON entry):

```
[17]: recipes = pd.read_json('data/recipeitems.json', lines=True)
recipes.shape
```

[17]: (173278, 17)

We see there are nearly 175,000 recipes, and 17 columns. Let's take a look at one row to see what we have:

```
[18]: recipes.iloc[0]
```

```
{'$oid': '5160756b96cc62079cc2db15'}
[18]: id
                                                Drop Biscuits and Sausage Gravy

      totalTime
                                                                             NaN
      creator
      recipeCategory
                                                                             NaN
      dateModified
                                                                             NaN
      recipeInstructions
                                                                             NaN
      Name: 0, dtype: object
```

There is a lot of information there, but much of it is in a very messy form, as is typical of data scraped from the web. In particular, the ingredient list is in string format; we're going to have to carefully extract the information we're interested in. Let's start by taking a closer look at the ingredients:

```
[19]: recipes.ingredients.str.len().describe()
```

```
[19]: count
                173278.000000
      mean
                   244.617926
      std
                   146.705285
                     0.00000
      min
      25%
                   147.000000
      50%
                   221.000000
      75%
                   314.000000
                  9067.000000
      max
```

Name: ingredients, dtype: float64

The ingredient lists average 250 characters long, with a minimum of 0 and a maximum of nearly 10,000 characters!

Just out of curiosity, let's see which recipe has the longest ingredient list:

```
[20]: recipes.name[np.argmax(recipes.ingredients.str.len())]
```

[20]: 'Carrot Pineapple Spice & Erownie Layer Cake with Whipped Cream & Cheese Frosting and Marzipan Carrots'

We can do other aggregate explorations; for example, we can see how many of the recipes are for breakfast foods (using regular expression syntax to match both lowercase and capital letters):

```
[21]: recipes.description.str.contains('[Bb]reakfast').sum()
```

[21]: 3524

Or how many of the recipes list cinnamon as an ingredient:

```
[22]: recipes.ingredients.str.contains('[Cc]innamon').sum()
```

[22]: 10526

We could even look to see whether any recipes misspell the ingredient as "cinamon":

```
[23]: recipes.ingredients.str.contains('[Cc]inamon').sum()
```

[23]: 11

This is the type of data exploration that is possible with Pandas string tools. It is data munging like this that Python really excels at.

1.3.1 A Simple Recipe Recommender

Let's go a bit further, and start working on a simple recipe recommendation system: given a list of ingredients, we want to find any recipes that use all those ingredients. While conceptually straightforward, the task is complicated by the heterogeneity of the data: there is no easy operation, for example, to extract a clean list of ingredients from each row. So, we will cheat a bit: we'll start with a list of common ingredients, and simply search to see whether they are in each recipe's ingredient list. For simplicity, let's just stick with herbs and spices for the time being:

We can then build a Boolean DataFrame consisting of True and False values, indicating whether each ingredient appears in the list:

```
[25]: import re
    spice_df = pd.DataFrame({
        spice: recipes.ingredients.str.contains(spice, re.IGNORECASE)
        for spice in spice_list})
    spice_df.head()
```

```
[25]:
                                                   rosemary
                                                              tarragon
                                                                         thyme
          salt
                pepper
                         oregano
                                    sage
                                          parsley
                                                                                paprika
      0 False
                 False
                           False
                                    True
                                            False
                                                       False
                                                                 False
                                                                         False
                                                                                  False
      1 False
                 False
                                            False
                                                       False
                                                                 False
                                                                         False
                                                                                  False
                           False
                                  False
```

| 2 | True | True | False |
|---|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| 3 | False |
| 4 | False |

cumin

- 0 False
- 1 False
- 2 True
- 3 False
- 4 False

Now, as an example, let's say we'd like to find a recipe that uses parsley, paprika, and tarragon. We can compute this very quickly using the query method of DataFrames, discussed further in High-Performance Pandas: eval() and query():

```
[26]: selection = spice_df.query('parsley & paprika & tarragon')
len(selection)
```

[26]: 10

We find only 10 recipes with this combination. Let's use the index returned by this selection to discover the names of those recipes:

```
[27]: recipes.name[selection.index]
```

[27]:	2069	All cremat with a Little Gem, dandelion and wa
	74964	Lobster with Thermidor butter
	93768	Burton's Southern Fried Chicken with White Gravy
	113926	Mijo's Slow Cooker Shredded Beef
	137686	Asparagus Soup with Poached Eggs
	140530	Fried Oyster Po'boys
	158475	Lamb shank tagine with herb tabbouleh
	158486	Southern fried chicken in buttermilk
	163175	Fried Chicken Sliders with Pickles + Slaw
	165243	Bar Tartine Cauliflower Salad

Name: name, dtype: object

Now that we have narrowed down our recipe selection from 175,000 to 10, we are in a position to make a more informed decision about what we'd like to cook for dinner.

1.3.2 Going Further with Recipes

Hopefully this example has given you a bit of a flavor (heh) of the types of data cleaning operations that are efficiently enabled by Pandas string methods. Of course, building a robust recipe recommendation system would require a *lot* more work! Extracting full ingredient lists from each recipe would be an important piece of the task; unfortunately, the wide variety of formats used makes this a relatively time-consuming process. This points to the truism that in data science, cleaning and munging of real-world data often comprises the majority of the work—and Pandas provides the tools that can help you do this efficiently.
